Neurological and psychiatric disorders contribute significantly to the global disease burden, adversely affecting the quality of life for both patients and their families. Impaired glutamatergic signaling is considered to be a major cause for most of the neurological and psychiatric disorders. Glutamate receptors are over-activated in excitotoxic conditions, leading to dysregulation of Ca^{2+} homeostasis, triggering the production of free radicals and oxidative stress, mitochondrial dysfunction and eventually cell death. Excitotoxicity primarily results from the overactivity of NMDARs, a subtype of ionotropic glutamate receptors, due to their pronounced Ca^{2+} permeability and conductance characteristics. NMDAR antagonists are suggested to have therapeutic use as they can prevent excitotoxicity. Our previous studies demonstrated lobeline, an alkaloid, averts neuroprotective actions in excitotoxic conditions by blocking NMDAR. However, the atomic level interaction of lobeline with NMDAR was not characterized yet. Structural comparison of lobeline with a known NMDAR antagonist desiprodil, followed by molecular docking and dynamic simulations revealed that lobeline could bind to the desiprodil binding site i.e., in the heteroameric interface of GluN1-GluN2B subunits and exert desiprodil like activities. By in silico structure-guided modifications on lobeline and subsequent free energy calculations, we propose putative NMDAR antagonists derived from lobeline.

Glutamate, the main excitatory neurotransmitter in the brain, plays a pivotal role in many brain processes including perception and cognition in the brain. This response is generated when glutamate interacts with its receptors. However, the excessive activation of glutamate receptors can lead to neuronal dysfunction and excitotoxicity^{1,2}. Excitotoxicity is a condition in the central nervous system (CNS) characterized by excessive neuronal death due to an increased influx of Ca^{2+} into the cell of post-synaptic animal and neuronal, primarily glutamate³. The excessive influx of glutamate is accompanied by the activation of ionotropic receptors and neurotoxic compounds like Ca^{2+} glutamate. Rapid activation by glutamate, in turn, leads to over-activation of ionotropic receptors that include N-methyl-D-aspartate (NMDA), ionotropic glycine, α -amino-3-hydroxy-5-methylisoxazole-4-propionate (AMPA) and kainate (KA) receptors^{4,5}. These ionotropic receptors are ligand-gated ion channels that are located on the cell membrane. The NMDA receptor (NMDAR) plays a pivotal role in both the structure and function of the nervous system, as well as in learning. The dysfunction of NMDARs is associated with CNS disorders including Huntington's disease, schizophrenia and Huntington's.

The NMDARs are calcium (Ca^{2+}) ions by glutamate-gated ion channels that are expressed in the CNS and were initially activated by the Ca^{2+} ions due to their high affinity Ca^{2+} permeability and conductance properties⁶. NMDARs have a unique binding site for which, initially, usually composed of two protein subunits, GluN1 subunit and NR2 subunit, forming GluN2A-43 subunits^{7,8}. Subsequent activation of NMDARs by AMPA and KA receptors leads to the influx of Ca^{2+} into the cell and subsequent activation of these processes leads to the activation of the signaling pathway in a cell, either through activation of enzymes or through the activation of a signaling pathway, including glutamatergic neurotransmission, leading to the activation of
